Identification of GutQ from *Escherichia coli* as a D-Arabinose 5-Phosphate Isomerase

Timothy C. Meredith\(^1\) and Ronald W. Woodard\(^1,2*,\)

Department of Medicinal Chemistry\(^1\) and Department of Chemistry,\(^2\) University of Michigan, Ann Arbor, Michigan 48109-1065

Received 14 June 2005/Accepted 27 July 2005

The glucitol operon (gut\(^{4EBDMRQ}\)) of *Escherichia coli* encodes a phosphoenolpyruvate:sugar phosphotransferase system that metabolizes the hexitol D-glucitol (sorbitol). The functions for all but the last gene, gutQ, have been previously assigned. The high sequence similarity between GutQ and KdsD, a D-arabinose 5-phosphate isomerase (API) from the 3-deoxy-D-manno-octulosonate (KDO)-lipopolysaccharide (LPS) biosynthetic pathway, suggested a putative activity, but its role within the context of the gut operon remained unclear. Accordingly, the enzyme was cloned, overexpressed, and characterized. Recombinant GutQ was shown to indeed be a second copy of API from the *E. coli* K-12 genome with biochemical properties similar to those of KdsD, catalyzing the reversible aldol-ketol isomerization between D-ribulose 5-phosphate (Ru5P) and D-arabinose 5-phosphate (ASP). Genomic disruptions of each API gene were constructed in *E. coli* K-12. TCM11[ΔkdsD] was capable of sustaining essential LPS synthesis at wild-type levels, indicating that GutQ functions as an API inside the cell. The gut operon remained inducible in TCM7[ΔgutQ], suggesting that GutQ is not directly involved in D-glucitol catabolism. The conditional mutant TCM15[ΔgutQ ΔkdsD] was dependent on exogenous ASP both for LPS synthesis/growth and for upregulation of the gut operon. The phenotype was suppressed by complementation in *trans* with a plasmid encoding a functional copy of GutQ or by increasing the amount of ASP in the medium. As there is no obvious obligatory role for GutQ in the metabolism of D-glucitol and there is no readily apparent link between D-glucitol metabolism and LPS biosynthesis, it is suggested that ASP is not only a building block for KDO biosynthesis but also may be a regulatory molecule involved in expression of the gut operon.

D-Arabinose 5-phosphate isomerase (API) is the first enzyme in the biosynthetic pathway of 3-deoxy-D-manno-octulosonate (KDO), a unique 8-carbon sugar component of lipopolysaccharide (LPSs). Lipopolysaccharides are amphiphilic macromolecules located in the outer leaflet of the outer membrane of gram-negative bacteria, forming an asymmetric lipid bilayer that surrounds the cell. The LPS layer is anchored in the outer membrane by the highly conserved lipid A domain and is followed by an oligosaccharide core region usually containing at least one KDO molecule that connects lipid A to an extended hypervariable repeating polysaccharide chain (O antigen) (25). In addition to providing a measure of intrinsic antibiotic resistance and defense against host responses, LPS (also referred to as endotoxin) is the main mediator of gram-negative bacterial pathogenesis (13, 33). The minimal LPS structure required for viability of *Escherichia coli* under laboratory conditions is KDO- lipid A, also referred to as Re endotoxin (11, 25, 31).

API catalyzes the reversible 1,2-keto/aldol isomerization of the pentose pathway intermediate ribulose 5-phosphate (Ru5P) to D-arabinose 5-phosphate (ASP) and is the intracellular source of ASP used for the formation of KDO in gram-negative bacteria. API is encoded by the kdsD (formerly *yrhH*) gene in *E. coli* K-12, though it was speculated that other APIs may exist in *E. coli* based on homology searches (20). In particular, the last open reading frame of the glucitol operon GutQ has significant homology (45% identity) to KdsD. The glucitol (sorbitol) operon expresses a phosphoenolpyruvate:sugar phosphotransferase system that is responsible for the uptake and catabolism of D-glucitol from the environment (24). The operon was originally studied by Lengeler (16, 17) and subsequently by Yamada and Saier (37, 38) and is known to consist of seven genes, *gut*\(^{4EBDMRQ}\) (Fig. 1). The EII\(^{Gut}\) complex is formed by GutA (EIIIC1 domain), GutE (EIIBC2 domains), and GutB (EIIBA domain) and transports D-glucitol across the inner membrane and into the cell as D-glucitol 6-phosphate. D-Glucitol 6-phosphate is then further metabolized by GutD, an NADH-dependent dehydrogenase (22), to the glycolytic intermediate D-fructose 6-phosphate. Expression of the gut operon is tightly controlled by a complex multicomponent regulatory system, consisting of a transcriptional repressor (GutR) and a transcriptional activator (GutM) in addition to cyclic AMP (cAMP)-catabolite activator protein-mediated regulation (39). However, the function of GutQ remains unknown (40). As there is no obvious obligatory role for GutQ in the metabolism of D-glucitol and there is no readily apparent link between D-glucitol metabolism and KDO biosynthesis, the study of both the in vitro and in vivo function of GutQ was undertaken to address the effects of GutQ on LPS biosynthesis and D-glucitol metabolism.

**MATERIALS AND METHODS**

**Materials.** Genomic *E. coli* K-12 MG1655 DNA was purchased from the American Type Culture Collection (ATCC 700926D). The Promega Wizard DNA purification kit was used for plasmid purification. Chemically competent *E. coli* XL1-Blue (Stratagene) and *E. coli* BL21(DE3) (Novagen) were used for...
cloning and protein expression, respectively. Sugars and sugar phosphates were purchased from Sigma-Aldrich, except for d-glucitol 6-phosphate, which was prepared by the sodium tetraborohydride reduction of the d-glucose 6-phosphate (G6P) (3), purified by anion-exchange chromatography (AG MP-1; Bio-Rad), and desalted by gel filtration (Bio-Gel P-2; Bio-Rad). Protein concentrations were determined using the Bio-Rad protein assay reagent with bovine serum albumin as the standard. Strains, plasmids, and primers are listed in Table 1.

Cloning, overexpression, and purification of GutQ. The gutQ gene was amplified using standard PCR methodology with the F-R primer pair (Table 1), digested with NdeI and BamHI, and directly ligated into similarly restricted linearized pT7-7 expression vector that had been treated with calf alkaline phosphatase. The ligation mixture was used to transform chemically competent E. coli XL1-Blue cells, and transformants harboring the pGQ1 plasmid were identified by restriction analysis and sequenced. E. coli BL21(DE3) cells were transformed with plasmid pGQ1 for protein expression.

E. coli BL21(DE3)/pGQ1 cells were grown in 25 mL medium containing ampicillin (100 µg/mL) at 37°C with shaking (250 rpm). Once the culture reached the mid-log growth phase (optical density at 600 nm of ~0.7 to 0.9), the culture was allowed to cool to 18°C before being induced with isopropyl-β-d-thiogalactoside at a final concentration of 0.4 mM. After 16 h of growth at 18°C, the cells were harvested by centrifugation (6,500 × g, 40 min, 4°C), and the supernatant was brought to 30% saturation. The protein pellet was suspended in 20 mL of buffer A (20 mM Tris-HCl, 1 mM dithiothreitol; pH 8.0) and sonicated on ice (five times for 30 seconds; 2-min pauses between pulses). Cellular debris was removed by centrifugation (29,000 × g, 40 min, 4°C), and the supernatant was filtered through a 0.22-μm Millex filter. The solution was loaded onto a Hi Load (16/10) Q-Sepharose fast flow column that had been washed with buffer A (200 mL). Fractions containing primarily recombinant GutQ were pooled and the protein concentration was determined using the Bio-Rad protein assay reagent with bovine serum albumin as the standard. Strains, plasmids, and primers are listed in Table 1.

Characterization of GutQ. The characterization of GutQ was performed according to methods reported for KdsD (20). Briefly, for substrate specificity enzyme samples were diluted in 100 mM Trizma-HCl buffer (pH 8.25) and assayed by initiating the reaction with substrate (15 nM GutQ, 10 mM sugar, 340 nm (22)). Enzyme solutions (100 nM Tris-HCl, pH 8.7, 5 mM NAD+) were preincubated at 25°C for 5 min before the reactions were initiated by the addition of d-glucitol 6-phosphate at a final concentration of 20 mM. Enzyme activity was determined by the discontinuous cysteine-carbazole colorimetric assay adapted to 96-well microplates as previously described (20). All plates contained internal Ru5P standards and appropriate A5P controls in triplicate.

A second, more sensitive coupled assay was developed to determine API activity in crude cell extracts that utilized 3-deoxy-D-manno-octulosonate 8-phosphate synthase (KdsA) from Arabidopsis thaliana (34). This enzyme catalyzes the irreversible stereospecific condensation of ASP and phosphoenolpyruvate to form 3-deoxy-D-manno-octulosonate 8-phosphate (KDOSP) and inorganic phosphate. Reaction mixtures containing 5 µL of a purified KdsA solution (3 mg/mL; 10 U/mg), 10 mM Ru5P, 0.6 mM phosphoenolpyruvate, and 1 mM EDTA in 40 µL of 100 mM Tris-HCl (pH 8.25) were incubated for 3 min at 37°C. The reaction was initiated by the addition of 10 µL of cell extract. After 5 min, reactions were quenched by adding 50 µL of 10% (wt/vol) trichloroacetic acid. The amount of KDOSP produced was determined by the Aminoff periodate-thiobarbituric acid assay (29). Under these conditions, KdsA was not rate limiting in the formation of KDOSP.

d-Glucitol 6-phosphate dehydrogenase (GutD) activity was measured using a continuous spectrophotometric assay by monitoring the formation of NADH at 340 nm (22). Enzyme solutions (100 nM Tris-HCl, pH 8.7, 5 mM NAD+) were preincubated at 25°C for 2 min before the reactions were initiated by the addition of d-glucitol 6-phosphate at a final concentration of 20 mM.

Characterization of GutQ. The characterization of GutQ was performed according to methods reported for KdsD (20). Briefly, for substrate specificity enzyme samples were diluted in 100 mM Trizma-HCl buffer (pH 8.25) and assayed by initiating the reaction with substrate (15 nM GutQ, 10 mM sugar, 1 mM EDTA). After 10 min at 37°C, reactions of mixtures containing the potential substrates d-arabinose, d-ribose 5-phosphate, G6P, d-glucose 1-phos-

![FIG. 1. The gut operon of E. coli K-12 MG1655. Genes that are highly conserved in both gram-negative and gram-positive bacterial gut operons are shaded dark gray while those that are specific to gram-negative bacteria are shaded light gray.](http://jb.asm.org/)
phate, α-glucosamine 6-phosphate, or α-mannose 6-phosphate were quenched, and the presence of ketose was determined. Product appearance for D/α-glycer-aldehyde 3-phosphate, D-erythrose 4-phosphate, and D-fructose 6-phosphate was assayed by SP nuclear magnetic resonance (NMR) (20). Kinetic constants were determined at 37°C using the discontinuous microplate assay and were initiated by the addition of substrate. Concentrations typically ranged from 0.2 Kₘ to 10 Kₘ. After 2 min, the reactions (50 mM Tris-Cl at pH 8.25, 5 nM GutQ, 1 mM EDTA) were quenched, at which point approximately less than 10% of substrate had been consumed. Initial rates were determined in triplicate and fitted to the standard Michaelis-Menten equation using nonlinear least-squares regression to determine Kₘ and vₐₚ values for both the formation and disappearance of Ru5P. The equilibrium constant (Kₑq) was determined using 31P NMR as described for KdsD (20). The pH optimum of GutQ was determined by diluting the enzyme in Bis-Tris propane buffer solutions of various pH values (pH 6.25 to 10, adjusted at 4°C). Activity was measured as outlined above in triplicate with a reaction time of 3 min (100 mM Bis-Tris propane, 15 nM GutQ, 10 mM ASP, 1 mM EDTA). Enzyme samples of GutQ as isolated were diluted in 100 mM Trizma-
HCl buffer (pH 8.25) and incubated with various divalent metals or EDTA for 30 min at 4°C. Remaining activity was then assayed at 37°C under saturating substrate conditions in triplicate with a 3-min reaction time (15 nM GutQ, 10 mM ASP, 10 μM metal or EDTA).

**Strain construction and growth conditions.** E. coli strain BW30270 was used as the host for chromosomal GutQ and kdsD disruptions using a phage λ Red recombinase system according to the procedure of Datensen and Wanner (7). Kanamycin and chloramphenicol were used at 50 μg/ml. Primer pairs GQF-GOR and KDF-KDR with either pKD13(kan) or pKD3(ori) as template, respectively, were used to construct insert cassettes targeting gutQ and kdsD. The resistance markers then were excised using the FLP recombinase system as described previously (7), and the deletion mutants are listed in Table 1. TCM15, containing deletions in both API genes, was similarly constructed from TCM13 using the GQF-GOR PCR product insert, except that medium and plates were supplemented at all times with G6P (10 μM) and ASP (15 μM) for subsequent manipulations performed after electrot transformation. All strains were used colony purified and tested for loss of all antibiotic resistances, and the relevant locus manipulations performed after electrotransformation. All strains used were colony purified and tested for loss of all antibiotic resistances, and the relevant locus was sequenced to confirm the expected deletion site.

Cultures were grown in either M9 minimal medium (27) or morpholinepropanesulfonic acid (MOPS) minimal medium (21) supplemented with thiamine (1 μg/ml) and the indicated carbon source(s) at 37°C with shaking (250 rpm). Cells were pelleted by centrifugation (8,000 × g, 20 min, 4°C). The cell pellets were re-suspended in buffer (20 mM Tris-HCl, 1 mM dithiothreitol, pH 8.0). Cells were disrupted by sonication and clarified by centrifugation (8,000 × g, 20 min, 4°C), and the supernatant fractions were aliquoted and stored at −20°C. Culture samples for LPS analysis were washed twice with Dulbecco phosphate-buffered saline, and the cell pellets were resuspended in lysis buffer (200 mM Tris, pH 6.8, 2% SDS, 4% 2-mercaptoethanol, 10% glycerol). Equal numbers of cells based on the optical density at 600 nm were processed according to the method of Hitchcock and Brown (14). Cells to be analyzed for RNA were rapidly resuspended in Max Bacterial Enhancement reagent (Invitrogen) and extracted using Trizol (Invitrogen) according to the manufacturer’s protocol. RNA samples were further purified by digestion with RNase-free DNase and isolated using the RNeasy mini kit (QIAGEN). The quality of the RNA was inspected by agarose gel electrophoresis and quantified by UV absorbance at 260 nm. Qualitative reverse transcription-PCR (RT-PCR) was performed using the Superscript II One-Step RT-PCR system (Invitrogen) as directed by the manufacturer with 1 pg of purified total RNA as template and GDF-GDR primers (0.2 μM) to amplify the first 342 bp of the gutD gene, and aliquots were removed for analysis after 35 cycles.

**RESULTS**

**Purification and characterization of recombinant GutQ.** Purification to homogeneity of recombinant GutQ was achieved in two steps using Q-Sepharose anion-exchange chromatography followed by ammonium sulfate precipitation. The protein appeared as a single band by SDS-PAGE (~33 kDa), and the specific activity was 329 U/mg with ASP as substrate. Monosaccharides that share common functionalities with ASP tested were assayed as potential alternative substrates for GutQ. In the cyto
tine-carbazole colorimetric assay, 2-ketohexoses and 2-ketopentoses form purple-red chromophores which absorb light at 540 nm (8). The conversion of aldo to ketose can be observed by measuring the increase in the ratio of absorbance at 540 nm of sample to control. None of the tested sugars (D-arabinose, D-ribose 5-phosphate, G6P, D-glucose 1-phosphate, D-glucosamine 6-phosphate, and α-mannose 6-phosphate) were converted by GutQ to their respective ketose forms (data not shown). Further, the short-chain phosphorylated aldoses D/1-glyceraldehyde 3-phosphate and D-erythrose 4-phosphate as well as D-fructose 6-phosphate did not serve as alternate substrates as determined by 31P NMR (data not shown). The biochemical properties of GutQ were determined to be quite similar to those of KdsD and are summarized in Table 2. The kinetic parameters, pH optima, lack of cofactor requirement, and quaternary structure were all comparable. Within the limits of detection, GutQ is a specific phosphosugar aldol-ketol isomerase for ASP and Ru5P.

**GutQ is capable of sustaining lipopolysaccharide biosynthesis.** To assess the ability of GutQ to function as an API in vivo, TCM7 and TCM11 were constructed using a red (γ, β, ε) homologous recombination system (7). Neither mutation was lethal, indicating the likely presence of multiple API-encoding genes that can provide sufficient quantities of ASP for LPS biosynthesis. LPS gel analysis indicated nearly equal amounts of the wild-type K-12 LPS core regardless of whether the gut operon was induced (Fig. 2A), indicating that ASP synthesis was not rate limiting in any of the strains under these growth conditions. Basal levels of GutQ (2 nmol/mg in comparison with 14 nmol/mg; see Table 3) in TCM11 were adequate to supply enough ASP to sustain viability and elaborate a functional LPS layer.

**LPS biosynthesis in ΔAPI strain TCM15.** Both gutQ and kdsD genes were able to be disrupted by using the G6P-inducible hexose phosphate transporter to supply exogenous ASP. ASP is a high-affinity, though noninducing, substrate of the hexose phosphate transport system (uph) (10). MOPS minimal medium, which has a low concentration of inorganic phosphate (1.3 mM), was used to prevent inhibition of uph-mediated transport by inorganic phosphate (28). The natural substrate of the uph system G6P was required for efficient induction and transport of ASP into the cells. ASP or G6P alone was unable to restore growth, as there was no detectable growth unless both ASP and G6P were included in the medium (Fig. 3A). GutQ and KdsD are thus the sole intracellular sources of ASP for KDO synthesis. Further, D-arabinose could not substitute for ASP (data not shown). Overnight cultures from which ASP had been exhausted from the medium were used to inoculate fresh cultures supplemented with various concentrations of ASP in order to enable lipopolysaccharide biosynthesis. After
were grown in M9 minimal medium containing dual carbon
sources, D-glucose and D-glucitol. All three strains grew at nearly identical rates (Fig. 2B) and exhibited the characteristic unusually long diauxic lag time of approximately 40 min after D-glucose had been exhausted from the medium (18). Under these conditions, induction does not appear to be influenced by the levels of GutQ. Strains BW30270, TCM7, and TCM11 were grown in M9 minimal medium with glycerol as the carbon source. Total API (KdsD and/or GutQ) and GutD specific activities were measured in all three strains (Table 3). The gut operon in both TCM7 and TCM11 remained inducible, with only an approximately two- to threefold difference in degree of induction as estimated by GutD activity compared to the isogenic wild-type BW30270 strain. API activity levels increased in both BW30270 and TCM11 when D-glucitol was added to the medium, indicating that GutQ was upregulated along with GutD. As expected, there was no change in observed API levels in TCM7 upon the addition of D-glucitol, though the strain remained capable of upregulating GutD. The majority of API activity (~90%) is attributable to KdsD in medium lacking D-glucitol, confirming the identification of KdsD as the constitutively expressed LPS pathway enzyme. TCM3 was used to investigate the effect of elevated API levels on the gut operon (Table 3). API specific activity was increased ~250-fold, but no appreciable difference was observed in GutD levels, as the

operon remained repressed unless d-glucitol was provided in the medium.

**ASP may be necessary for upregulation of the gut operon.**

Since no difference was observed in the regulation of the gut operon when a single API gene was disrupted, failure to directly observe the effect may have been due to suppression by the second copy of API. The inducibility of the gut operon was investigated in TCM15. Overnight cultures were grown in MOPS minimal medium with thiamine (1 μg/ml) and glycerol (0.1%) as sole carbon source. Sugar phosphates were supplemented in the medium with either 10 μM G6P (Δ), 15 μM ASP (□), or both (○). (B) Correlation of LPS with concentration of ASP. A stationary-phase culture grown in MOPS minimal medium (0.2% glycerol, 5 μM ASP, 10 μM G6P) that had ceased dividing was diluted into fresh medium containing G6P (10 μM) and various concentrations of ASP (0.1, 1, 10, 50, and 100 μM) and shaken for 6 h. LPS samples were prepared from the same number of cells based on optical density at 600 nm and analyzed by Tricine SDS-PAGE and silver staining. (C and D) LPS Tricine SDS-PAGE (C) and qualitative RT-PCR transcript analysis (D) of gutD in samples prepared from wild-type BW30270 (lanes 1 and 2) and TCM15 (lanes 3 and 4). TCM15 was preinduced with 10 μM G6P and 5 μM ASP, pelleted, resuspended in fresh MOPS minimal medium (0.2% glycerol) with only ASP and 10 mM d-glucitol as indicated, and shaken for an additional 4 h before harvesting for analyses. Lane S, 0.1- to 1-kb DNA molecular size markers; lane Con, genomic DNA as template.

The essential nature of LPS in most gram-negative bacteria has attracted much attention towards developing specific antibiotics targeting enzymes involved in its synthesis. Substantial progress in elucidating the genes of the LPS biosynthetic pathway has been achieved, particularly with KDO, for which each gene has been assigned (25, 32, 35). The minimal lipopolysaccharide structure required for viability in *E. coli* is lipid A-KDO₂ (25, 31). However, the construction of the viable mutant TCM11 from this pathway prompted further investigation of the function of other API homologues and their potential relationship to LPS biosynthesis in *E. coli*.

**DISCUSSION**

Homology searches identified GutQ as a prime candidate based on the high degree of sequence similarity to KdsD (20, 32). Further, GutQ shares the same domain architecture with KdsD, namely, an N-terminal catalytic isomerase domain followed by a pair of CBS (cystathionine β-synthase) domains (2). Indeed, GutQ is the namesake of the “GUTO” isomerase domain listed in the NCBI Conserved Domain Databases that is common to all APIs characterized to date. This homology extends into their similar biochemical properties as well (Table 2). To avoid confusion in nomenclature between these two paralogues, it is suggested that GutQ be referred to as G-API (G = glucitol) and KdsD as L-API (L = lipopolysaccharide).

The rate of LPS biosynthesis has been correlated with the
rate of KDO production, which in turn is believed to be limited by CMP-KDO synthetase (~2 nmol KDO/min/mg) (26). The API levels in TCM11 are approximately the same, indicating that basal levels of G-API alone may be sufficient to maintain wild-type levels of flux through the KDO pathway. In agreement, no discernible differences were seen in the amounts of LPS in either TCM11 or TCM7 (Fig. 2A). LPS levels do, however, become dependent upon the concentration of A5P in cultures of TCM15 that had been preinduced for uhp-mediated transport. Cultures not induced for A5P uptake ceased dividing within a few generations, proving that the ΔAPI genotype is conditionally lethal in E. coli. The titratable nature of the K-12 LPS core in TCM15 provides the unique ability to control the ratio of mature wild-type LPS to LPS precursors by varying the amount of A5P in the medium. Many LPS precursors, in particular lipid IVa (6), are known to be antagonists of endotoxin-induced septic shock, and conditional mutants in LPS biosynthesis are potentially useful resources in potential vaccine/adjuvant development (23, 36). The potency of any developed or future KDO pathway competitive inhibitors (4, 9, 12, 15), long considered a drug target in vivo, suggests that a pentose phosphate isomerase is a specific regulatory enzyme of the gut operon. The physiological function of G-API may be to synthesize the regulatory molecule A5P, which in turn participates in the induction of the gut operon through an unknown mechanism. It is unclear why no effect was observed in either single API knockout strain. Suppression due to the sec-dependent API genotype and induction may become subject to the concentration of A5P only under certain growth conditions. Further work is needed to define the complex regulatory system of the gut operon.

ACKNOWLEDGMENTS

This research was supported by the Pfizer Fellowship in Medicinal Chemistry (T.C.M.) and the Chemical Biology Interface (CBI) training grant (T.C.M.).

We thank Ted Houston of the University of Michigan Department of Geology at the W. M. Keck Elemental Geochemistry Laboratory for measuring metal content. We also thank other members of the Woodard group for helpful discussions.
