Received for publication 21 September 1967

The synthesis of citric and glutamic acids by extracts of Chloropseudomonas ethylicum was studied with labeled precursors. When acetyl-coenzyme A-1-14C was used as substrate, only 0.1% of the total radioactivity was found in the C-5 position of citric acid; whereas, with oxalacetate-4-14C as substrate, 100% of the total radioactivity was found in C-5. These results demonstrated that the Chloropseudomonas citrate synthetase had an absolute stereospecificity, identical to that of the pig heart synthetase. The distribution of radioactivity in the glutamic acid synthesized from acetyl-coenzyme A-1-14C was 0% in C-1 and 94.0% in C-5; whereas the glutamic acid formed from oxalacetate-4-14C contained 89.6% in C-1 and 0.5% in C-5. This distribution is entirely consistent with the biosynthesis of glutamic acid from citric acid via aconitate, D₃-isocitrate, and L-glutamate dehydrogenases. The presence of L-glutamate dehydrogenase in extracts was demonstrated. The stereospecificity of the citrate synthetase and the pattern of glutamate labeling further establish that the aconitate of Chloropseudomonas is completely stereospecific.

Recent studies have shown that the citrate synthetase of some species of anaerobic bacteria possesses an unusual stereospecificity. This was first revealed by Gottschalk and Barker (7), who found that the citrate synthetase of Clostridium kluyveri had essentially the reverse, or unusual, stereospecificity of that found for the pig heart enzyme (9). On the other hand, Stern, Hegre, and Bambers (11), using a different strain of C. kluyveri, found that the citrate synthetase displayed the usual stereospecificity. However, both groups found that about 5 to 8% of the radioactivity of the labeled precursors, oxalacetate-4-14C and acetate-1-14C, did translocate to the opposite carboxyl of glutamate to that predicted from an absolutely stereospecific course of citrate synthesis. Gottschalk and Barker (8) have shown that three other anaerobic bacteria (C. acidi-urici, C. cylindrosorum, and Desulfovibrio vulgaris) possess a citrate synthetase with the unusual or reverse stereospecificity. Five other anaerobes examined, including two other species of Clostridium, possessed the usual type of citrate synthetase.

Callely and Fuller (2) have reported the presence of citrate synthetase, aconitate, and D₃-isocitrate dehydrogenase in cell extracts of Chloropseudomonas ethylicum, a green obligately photosynthetic anaerobic microorganism. Like C. kluyveri, it requires both CO₂ and acetate (or a precursor of acetate, e.g., ethyl alcohol) as carbon sources for growth; whereas C. kluyveri derives its reducing power by alcohol oxidation, C. ethylicum utilizes the photosynthetic process. It was therefore of interest to examine the stereospecificity of the citrate synthetase of C. ethylicum.

The results reported in this paper demonstrate that Chloropseudomonas citrate synthetase is absolutely stereospecific and has the usual stereospecificity, identical to the pig heart enzyme. In addition, the presence of L-glutamate dehydrogenase has been demonstrated, and it is shown that glutamate biosynthesis from labeled precursors does occur via the citrate pathway.

MATERIALS AND METHODS

Organisms and growth conditions. A lyophilized preparation of C. ethylicum, which had been grown as described (2), was kindly provided by R. C. Fuller. Aerobacter aerogenes NCTC 418 was grown on the citrate medium of Dagley and Dawes (4) and C. tetanomorphum H1 was grown as described by Barker et al. (1).

Preparation of cell extracts. Cell extracts were prepared by hand grinding 0.5 g of lyophilized Chloropseudomonas cells with 3 g of glass beads (size 12) for 5 min at 5 C in 1 ml of 0.05 M tris(hydrox-
(3-Methyl)aminomethane (Tris)-chloride buffer (pH 7.4) containing 0.02 M 2-mercaptoethanol. An additional 4.0 ml of buffer was added, and the suspension was centrifuged for 20 min at 27,000 × g at 0 C. A. aerogenes extract was prepared by treating 3 g of wet cells in 10 ml of 0.2 M Tris-chloride buffer (pH 8.0) for 3 min at 5 C with a Branson Sonifier. Cell debris was settled by centrifugation as described above.

Enzyme assays. Citrate synthetase was assayed according to the procedure of Stern et al. (12). Glutamate dehydrogenase was measured spectrophotometrically at 340 nm by (i) the oxidation of reduced nicotinamide adenine dinucleotide phosphate (NADPH) in the presence of α-ketoglutarate and NH₄Cl and (ii) the reduction of nicotinamide adenine dinucleotide phosphate (NADP) by L-glutamate.

Materials. E. coli L-glutamate decarboxylase was obtained from Worthington Biochemical Corp. (Freehold, N.J.) and glutamate-oxalacetate transaminase from Boehringer & Co. Acetyl-coenzyme A (CoA)-1-14C was a product of New England Nuclear Corp. (Boston, Mass.) and aspartic acid-4-14C was a product of Calbiochem (Los Angeles, Calif.).

Synthesis of radioactive citric and glutamic acids from aspartyl-CoA-1-14C. The reaction mixture contained: Tris-chloride buffer (pH 7.4), 100 μmoles; potassium oxalacetate, 20 μmoles; acetyl-CoA-1-14C 5 μmoles (2.5 μC); and Chloropseudomonas extract, approximately 20 mg of protein in a total volume of 1.8 ml.

Synthesis of radioactive citric and glutamic acids from aspartic acid-4-14C. The reaction mixture contained: Tris-chloride buffer (pH 7.4), 100 μmoles; potassium α-ketoglutarate, 25 μmoles; acetyl-CoA, 5 μmoles; aspartic acid-4-14C, 5 μmoles (2.5 μC); glutamate-oxalacetate transaminase, 0.2 mg; and Chloropseudomonas extract, approximately 20 mg of protein in a total volume of 1.8 ml.

Ammonia, NADP, and Mg²⁺ were deliberately omitted from both of the reaction mixtures to minimize further metabolism of citrate via aconitase, isocitrate, and glutamate dehydrogenases. However, trace amounts of these compounds in the crude cell extract permitted some glutamate formation from accumulated citrate. Both reactions were run in air at 30 C for 10 min and were terminated by heating at 100 C for 3 min. The clear supernatant solutions were placed on Whatman 3 MM paper and were chromatographed in sec-butyl alcohol-formic acid-water (67:11:22). The radioactive citric and glutamic acids were located on a strip scanner and were eluted with 10 ml of water. The glutamic acid was further purified by electrophoresis on Whatman 3 MM paper in pyridine-acetic acid (pH 3.5) for 3 hr at 2,700 v. The citric acid, which gave only a single radioactive spot after chromatography in two different solvent systems, was used without further purification.

Degradation of radioactive citric and glutamic acids. Citric acid-4-14C was incubated with an extract of A. aerogenes containing citratase and oxalacetate decarboxylase (3) and was thereby almost quantitatively converted to CO₂ (C-5), pyruvate (C-4, C-3, C-6), and acetate (C-1 and C-2). The incubation was carried out in Warburg flasks containing: Tris-chloride buffer (pH 8.0), 100 μmoles; potassium citrate, 5 μmoles; and citric acid-4-14C, and 0.1% of the

Results

Glutamate dehydrogenase. As shown in Table 1, cell-free extracts of Chloropseudomonas were capable of oxidizing NADPH in the presence of α-ketoglutarate and ammonium chloride. There was essentially no oxidation of reduced nicotinamide adenine dinucleotide (NADH₂) under the same conditions. When α-ketoglutarate or ammonium chloride were omitted, no oxidation of NADPH occurred. Cell extracts were also capable of reducing NADP, but not nicotinamide adenine dinucleotide (NAD), in the presence of L-glutamate. Thus, L-glutamate dehydrogenase, which catalyzes the following reaction, was present in the extracts:

L-glutamate + NADP\(^{+}\) + α-ketoglutarate + NADPH₂ + H⁺

The rate of the reverse reaction was approximately 15 times faster than the rate of the forward reaction. The observed activity of L-glutamate dehydrogenase represents a minimal value, since the specific activity of the citrate synthetase of the lyophilized cell extract was only 25% of the value given by Calley and Fuller (2) for frozen cell extracts. It was also noted that sonic treatment of lyophilized cells, even in the presence of mercaptoethanol, resulted in almost complete loss of citrate synthetase activity.

Labeling of citric acid. The C-5 of citrate was converted to CO₂ as described. When acetyl-CoA-1-14C was the precursor, only 0.1% of the
total radioactivity was found in C-5; whereas, when oxalacetate-4-14C was the precursor, 100% of the radioactivity was present in C-5 (Table 2).

Labeling of glutamic acid. The distribution of radioactivity in glutamic acid synthesized by cell extracts is shown in Table 3. With acetyl-CoA-1-14C as precursor, 94% of the total radioactivity of glutamic acid was found in C-5 and none in C-1. The γ-aminobutyrate fragment (C-2 to C-5), which was shown by chromatographic analysis to be the only residual product resulting from the decarboxylase action, had 89.6% of the total radioactivity of the glutamate. Clearly, this radioactivity was confined to C-5 of glutamate. When oxalacetate-4-14C was the precursor, the labeling pattern of glutamate showed 89.6% of the radioactivity in C-1 and 0.5% in C-5. The γ-aminobutyrate fragment was not radioactive, and, therefore, it can be concluded that no significant radioactivity entered C-5 of glutamate.

Chromatographic analysis also showed that minor amounts of radioactive malate, fumarate, and succinate had been formed after incubation of the cell extracts with oxalacetate-4-14C. Since Calley and Fuller (2) have found all the enzymes of the citric acid cycle, except α-ketoglutarate dehydrogenase, in Chloropseudomonas, these com-

![Fig. 1. Pathway of conversion of acetyl-CoA-1-14C (14C) and oxalacetate-4-14C (2-14C) to glutamate via citrate. The numbers refer to the C atoms of citrate which is written in the Fischer projection with the – COOH group on top and the oxalacetate-derived aconitate-active – CH2COOH group on the bottom, and with both projecting behind the plane of the paper.](http://jb.asm.org/)

pounds probably arose by conversion of oxalacetate-14C via the stepwise activities of L-malate dehydrogenase, fumarase, and succinate dehydrogenase.

**DISCUSSION**

Calley and Fuller (2) have demonstrated that extracts of Chloropseudomonas possess all the enzymes of the citric acid cycle, with the exception of α-ketoglutarate dehydrogenase. No
attempt was made by these workers to determine whether glutamate dehydrogenase was present, but the enzymes of the glyoxylate cycle could not be detected. We have demonstrated the presence of glutamate dehydrogenase in cell-free extracts, thus indicating that synthesis of glutamic acid is possible via the citric acid cycle mechanism. This result has been further confirmed by the finding that Chloropseudomonas extract synthesized radioactive citric and glutamic acids from acetyl-CoA-1-14C and oxalacetate-4-14C. The fact that the organism does not have a complete citric acid cycle indicates that citrate synthetase, aconitate, isocitrate, and glutamate dehydrogenases constitute a biosynthetic route for the formation of glutamic acid.

The usual stereospecific course of citrate synthesis (Fig. 1) from acetyl-CoA-1-14C and oxalacetate leads to the formation of citric acid-1-14C which is converted via aconitate, isocitrate, and glutamate dehydrogenases to glutamic acid-5-14C; when acetyl-CoA and oxalacetate-4-14C are the precursors, then the products are citric acid-5-14C and glutamic acid-1-14C. The results of experiments with Chloropseudomonas extract (Tables 2 and 3) are essentially in accord with this formulation. Thus, one can conclude that the citrate synthetase of Chloropseudomonas has the usual stereospecificity (identical to pig heart synthetase) and is 100% stereospecific. It is noteworthy that no translocation of carbon radioactivity occurs on conversion of labeled acetate or oxalacetate to glutamate, as was seen in C. kluyveri (7, 10, 11). In this respect, Chloropseudomonas duplicates the behavior of C. thermoaerophilum (J. R. Stern, Bacteriol. Proc., p. 75, 1966).

It can also be concluded from the data in Table 3 that the aconitate of Chloropseudomonas is 100% stereospecific and is identical to pig heart aconitate (5, 9).
