Received 20 June 1996/Accepted 5 August 1996

We have identified a gene cluster located on the chromosomal *Sma*I I fragment of a highly methicillin resistant strain of *Staphylococcus aureus*, consisting of four open reading frames (ORFs), named after the number of deduced amino acid residues, in the sequential order orf333-orf108-orf159-orf256. The gene cluster showed close similarities to the *Bacillus subtilis sigB* operon both in overall organization and in primary sequences of the gene products. The complete gene cluster (provisionally named sigma-B or *sigB*) was preceded by an  $\sigma^A$ -like promoter ( $P_A$ ) and had an internal  $\sigma^B$ -like promoter sequence ( $P_B$ ) between orf333 and orf108, suggesting a complex regulatory mechanism. The polypeptides encoded by orf333, -108, -159, and -256 showed 62, 67, 71, and 77% homologies, respectively, with the RsbU, RsbV, RsbW, and SigB polypeptides encoded by the *B. subtilis sigB* operon. A Tn551 insertional mutant, RUSA168 (insert in orf256 of the staphylococcal sigma-B operon), showed drastic reduction in methicillin resistance (decrease in MIC from 1,600  $\mu\text{g ml}^{-1}$  to 12 to 25  $\mu\text{g ml}^{-1}$ ).

Bacteria have evolved adaptive networks to face the challenges of changing environment and to survive under conditions of stress (27). One of the stress conditions most frequently encountered by bacteria is a suboptimal nutritional milieu, leading to a stationary phase of growth. Drastic changes in cellular physiology and morphology accompany the onset of bacterial stationary phase: there are structural changes in the cell envelope, differences in DNA supercoiling and compactness, synthesis of storage compounds and protective substances, modification of DNA polymerase core, etc. (12). The molecular mechanisms of these changes require expression of a number of new genes, and the expression of many of these genes is controlled by the association of alternative sigma factors with the catalytic core of RNA polymerase (10, 11, 15, 16). The alternative or minor sigma factors are activated early in the stationary growth phase to confer different promoter recognition specificities on the polymerase holoenzyme and reprogram the pattern of gene expression in response to environmental signals (11). No alternative sigma factor has so far been identified in *Staphylococcus aureus*, and we are not aware of any reports in the literature describing the involvement of stress response genes in the expression of antibiotic resistance. In this report, we describe a chromosomal gene cluster in a methicillin-resistant strain of *S. aureus*, the gene products of which are highly homologous with those of the sigma-B operon in *Bacillus subtilis* (27), an operon that is believed to define an alternative sigma factor regulating bacterial metabolism in response to environmental stress in the stationary phase (3, 4, 8). Insertional inactivation by transposon Tn551 in this region of the staphylococcal chromosome has generated a group of mutants (RUSA168, RUSA150, and RUSA122) with drastic reduction in resistance to methicillin, suggesting that an intact

stress response system is essential for the optimal expression of antibiotic resistance in these bacteria.

## MATERIALS AND METHODS

**Bacterial strains, phage, and plasmids.** The bacterial strains, phage, and plasmids used in this study are described in Table 1.

**Media and growth conditions.** *S. aureus* and methicillin-resistant *S. aureus* mutants were grown in tryptic soy broth (Difco Laboratories) with aeration as described previously (18). Luria-Bertani medium was used to propagate *Escherichia coli* DH5 $\alpha$ , and ampicillin (100  $\mu\text{g ml}^{-1}$ ) was added for selection and maintenance of the plasmids listed in Table 1. *E. coli* XL1-Blue MRA and MRA(P2) were the host cells for Lambda DASHII phage. They were cultured as recommended by the supplier (Stratagene Cloning Systems, La Jolla, Calif.).

**Antimicrobial susceptibility testing.** Overnight cultures grown in tryptic soy broth in which various dilutions of the bacterial cultures were plated at 37°C with aeration were used for testing the expression of methicillin resistance, using the method of population analysis in which various dilutions of the bacterial cultures are plated on tryptic soy agar containing increasing concentrations of methicillin (5). Colonies were counted after incubation at 37°C for 48 h.

**DNA methods.** All routine DNA manipulations were performed as described in reference 21 and 1. Restriction enzymes, calf intestine alkaline phosphatase, and T4 DNA ligase were purchased from New England Biolabs, Inc., and used as recommended by the manufacturer. Southern analysis was performed with ECL random prime labeling and detection systems (Amersham Life Science) as recommended by the manufacturer.

**DNA sequence analysis.** Double-stranded DNA sequencing was accomplished by the dideoxy-chain termination method (22) with templates of DNA fragment cloned in pGEM-3Z. The oligonucleotide primers were synthesized and purified by Genosys Biotechnologies, Inc. Sequenase 2.0 (United States Biochemical) was used for chain elongation, and [<sup>35</sup>S]dATP-labeled samples were run in 8 M urea-6% polyacrylamide gels. Nucleotide and derived amino acid sequences were analyzed with the Wisconsin Genetics Computer Group software.

## RESULTS

**Reduction of methicillin resistance in Tn551 insertional mutants RUSA122, -150, and -168.** The insertional mutants had drastically reduced resistance to methicillin. The MICs of Tn551 mutants RUSA168, -122, and -150 decreased from the MIC of the parental strain (1,600  $\mu\text{g ml}^{-1}$ ) to 25, 50, and 50  $\mu\text{g ml}^{-1}$ , respectively (5).

**Cloning the  $\Omega$ 727/729 region.** The Tn551 insertion sites  $\Omega$ 727 and  $\Omega$ 729, which generated the insertional mutants

RUSA168 and RUSA122, respectively, were found to be located on a 9.8-kb *EcoRI* DNA fragment of the COL chromosome (5). The 15-kb *EcoRI* fragments including transposon Tn551 were purified from strains RUSA168 and RUSA122 and then cloned into the Lambda DASHII/*EcoRI* phage vector

as previously described (29). The recombinant lambda phages were named  $\lambda$ DII/R168 and  $\lambda$ DII/R122, respectively. The physical maps of the DNA inserts in  $\lambda$ DII/R168 and  $\lambda$ DII/R122, determined by restriction digestions and Southern hybridization (Fig. 1a and e), showed that  $\Omega$ 727 and  $\Omega$ 729 were

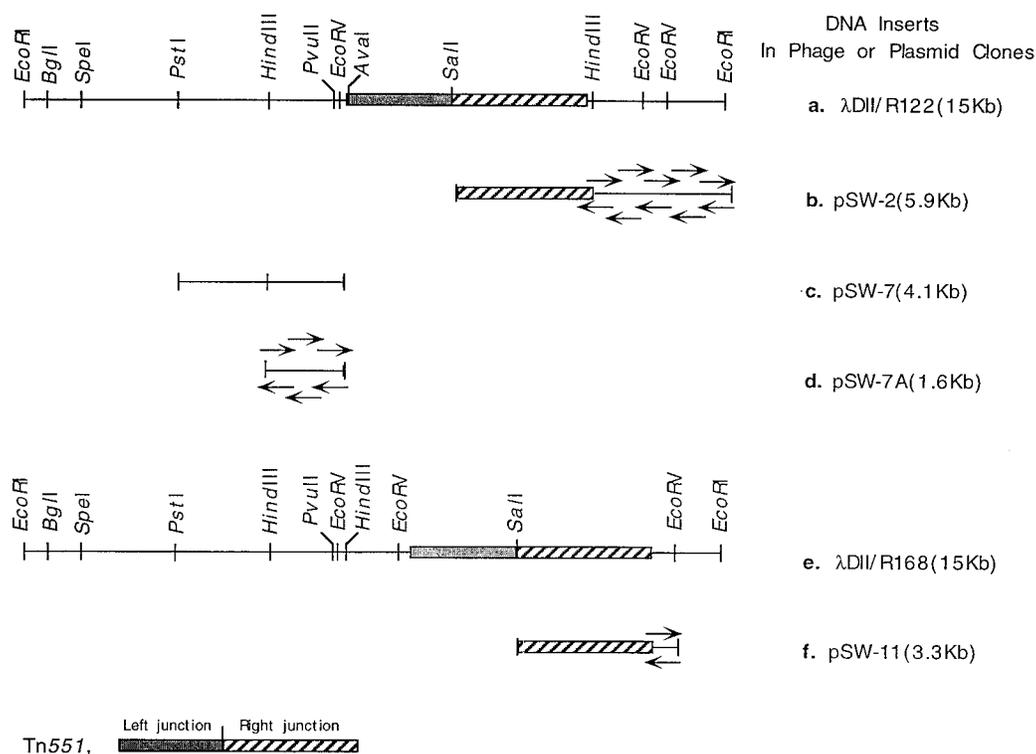

FIG. 1. Restriction map and strategy for sequencing of the  $\Omega$ 727/729 region. (a) Restriction map of the 15-kb DNA insert in  $\lambda$ DII/R122. Transposon Tn551 is shown as a box. (b) The 5.9-kb DNA insert in pSW-2. The striped box represents the Tn551 right junction, and the arrows indicate the direction of sequencing. (c) The 4.1-kb DNA insert in pSW-7. FIG. 2. Nucleotide sequence of the 4,607-bp *Hind*III-*Eco*RI fragment containing the  $\Omega$ 727/729 region. Numbering starts at the *Hind*III site and ends at the *Eco*RI site (position 4607). The putative start codon is indicated below the gene designation, and the stop codon is designated with an asterisk. A putative Shine-Dalgarno (S.D.) sequence is underlined. The possible candidates for promoter sequences (-35 and -10 regions) are shown, and the pairs of -10 and -35 regions belonging to one possible consensus are indicated with same letter designation, e.g., -35a and -10a. Inverted repeat sequences are indicated by arrows. The insertion sites of Tn551 are shown by underlining of the two spanning nucleotides and labeled  $\Omega$ 727 and  $\Omega$ 729. Amino acids deduced from the nucleotide sequence are specified by standard one-letter abbreviations.

located on the same 9.8-kb *Eco*RI fragment but different *Hind*III (4 kb for  $\Omega$ 727 and 1.9 kb for  $\Omega$ 729) and *Eco*RV (about 0.6 kb for  $\Omega$ 727 [the Tn551 insertional site  $\Omega$ 728 of RUSA150 was determined to be on the same *Eco*RV fragment as  $\Omega$ 727] and 1.4 kb for  $\Omega$ 729) fragments. The *Pst*I, *Pvu*II, *Spe*I, and *Bgl*I recognition sites on the flanking sequence of Tn551 were also mapped with respect to the unique *Sal*I restriction site of Tn551 (Fig. 1a and e).

The 4.1-kb *Ava*I-*Pst*I fragment of  $\lambda$ DII/R122, which includes a 7-bp Tn551 left junction and 4.1-kb  $\Omega$ 729 left flanking region, was subcloned into *Ava*I-*Pst*I-digested pGEM-3Z to form the recombinant plasmid pSW-7 (Fig. 1c). pSW-7 was subsequently digested with *Hind*III, the 4.3-kb fragment was separated from the 2.0-kb fragment, and plasmid pSW-7A was generated by self-ligation of the 4.3-kb fragment (Fig. 1d). Plasmid pSW-2 was constructed by ligating the 5.9-kb *Sal*I fragment of  $\lambda$ DII/R122 with *Sal*I-digested pGEM-3Z vector. The insert DNA in pSW-2 included a 2.9-kb Tn551 right junction and 3.0-kb  $\Omega$ 729 right flanking region (Fig. 1b); actually this insert had spanned the insertion site  $\Omega$ 727, according to the physical map (Fig. 1a and e). In addition, the 3.3-kb *Sal*I-*Eco*RV fragment of  $\lambda$ DII/R168 was subcloned into pGEM-3Z vector to create plasmid

pSW-11 (Fig. 1f); thereby the right flanking region of  $\Omega$ 727 with a 2.9-kb Tn551 right junction was also isolated.

**DNA sequencing of the  $\Omega$ 727/729 region.** The DNA sequence of the  $\Omega$ 727/729 region was determined by separately sequencing the DNA inserts of pSW-7A and pSW-2 through both strands, using the strategy of primer walking. In the 4,607-bp DNA sequence depicted in Fig. 2, the sequence of the first 1,633 bp of the 5' portion was obtained from sequencing of the pSW-7A insert DNA which covered the area between the *Hind*III cloning site and the insertion site  $\Omega$ 729 (Fig. 1d); the 2,974-bp region of the 3' portion from bp 1634 to 4607 was the region from the insertion site  $\Omega$ 729 to the *Eco*RI cloning site of  $\lambda$ DII/R122 (Fig. 1b), and this was a part of the insert DNA in pSW-2.

The 4,607-bp region was analyzed for open reading frames (ORFs). As shown in Fig. 2 and 3, this region contained six ORFs (one truncated by an *Eco*RI cloning site in the C terminus), which were tentatively designated according to the number of deduced amino acid residues in the order orf136-orf333-orf108-orf159-orf256-CTorf239 (CT, C-terminally truncated). orf136 was initiated with a typical ATG codon, but no multiple guanine sequence which could be considered a ribo-

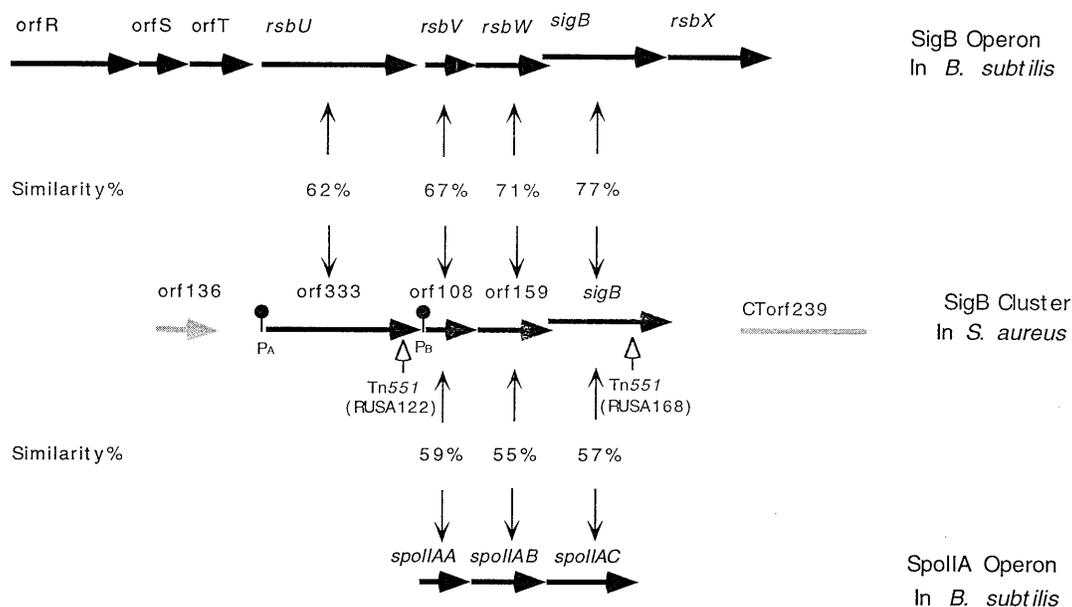

FIG. 3. Similarity in organization of the *S. aureus* *sigB* cluster and the *B. subtilis* *sigB* and *spoIIA* operons. In the physical maps of the *sigB*, *sigB*, and *spoIIA* operons, ORFs are indicated by arrows. *sigB* encodes the stationary-phase alternative sigma factor in *B. subtilis*, and *spoIIA* encodes the sporulation-essential  $\sigma^F$  in *B. subtilis*. Similarities between the predicted products of the corresponding genes are shown with percentages. The two Tn551 insertion sites ( $\Omega 727$  and  $\Omega 729$ ) in the *S. aureus* *sigB* cluster are indicated with arrows.

orf159-orf256 showed a high degree of similarity to the *rsbU*-*rsbV*-*rsbW*-*sigB* cluster in the *B. subtilis* *sigB* operon (Fig. 3); the polypeptides encoded by orf333 (38 kDa), orf108 (12 kDa), orf159 (18 kDa), and orf256 (29 kDa) were correspondingly homologous with the products of the 334-residue RsbU, 109-residue RsbV, 160-residue RsbW, and 264-residue SigB (62, 67, 71, and 77% similarities) (Fig. 3 and 4). The *B. subtilis* *spoIIA* operon consists of three genes, *spoIIAA*, *spoIIAB*, and *spoIIAC*, with *spoIIAC* encoding the sporulation-essential  $\sigma^F$  (9, 19, 24, 25). The similarity in organization of the *spoIIA* operon and the ORFs in the  $\Omega 727/729$  region was evidenced by the fact that the products of *spoIIAA*, *spoIIAB*, and *spoIIAC* had similarities of 59, 55, and 57% to the products of orf108, orf159, and orf256 (Fig. 3).

Furthermore, the glycine residue (Gly-93) important for RsbV function (4) was conserved in orf108 product (Fig. 4b). Also conserved in the orf159 product was Ala-14 in RsbW (Fig. 4c). The orf136 and CTorf239 products had no significant similarity with any protein in the Tblastn and Blastp databanks.

## DISCUSSION

Comparison of amino acid sequences has shown that the gene cluster in the *S. aureus*  $\Omega 727/729$  region is highly homologous with the *sigB* and *spoIIA* operons of *B. subtilis* (Fig. 3 and 4) and that there is a high degree of similarity between the products of *S. aureus* orf333, orf108, orf159, and orf256 and their counterparts *rsbU*, *rsbV*, *rsbW*, and *sigB* in the *sigB* operon of *B. subtilis* (Fig. 3 and 4). *B. subtilis* *rsbU* is also known to have high degree of similarity to *spoIIIE* (7). Therefore, there may also be a functional similarity between *spoIIIE* and orf333. The similarities in both product sequence and overall genetic organization suggest that the gene cluster in the  $\Omega 727/729$  region may be regulated in a manner similar to that of the *sigB* operon of *B. subtilis*. We infer that orf256, which encodes a polypeptide of about 29 kDa (29,443 Da) and corresponds to the *sigB* structural gene, is the corresponding structural gene of

the staphylococcal orf333-orf108-orf159-orf256 cluster. We propose to name this cluster the sigma-B operon, to name orf256 the *sigmaB* gene, and to name the product of orf256 the  $\sigma^B$  factor.

Several observations suggest that the staphylococcal *sigB* and *B. subtilis* *sigB* operons may perform similar physiological roles. (i) There are close similarities between the four genes of the *S. aureus* *sigB* cluster and their counterparts in the *B. subtilis* *sigB* operon. (ii) The gene *rsbU* is believed to encode a *trans*-acting, positive regulatory factor that controls  $\sigma^B$  (28). We speculate that orf333 and *sigB* correspond to an analogous pair of positive regulator and structural genes in *S. aureus*. This conclusion is consistent with the less severe reduction in antibiotic resistance level in mutant RUSA122 (Tn551 insert of orf333) compared with the substantially lower methicillin MIC ( $25 \mu\text{g ml}^{-1}$ ) in mutant RUSA168 (Tn551 insert in *sigB*). (iii) The staphylococcal *sigB* operon may also be preceded by two promoters: the putative upstream promoter of orf333 may have a function similar to that of the *B. subtilis* *sigB*  $P_A$ ; the putative downstream promoter of orf333 is identical to most  $\sigma^B$ -dependent promoters (26) in the  $-10$  region (GGGTAT) and might be an internally  $\sigma^B$ -dependent promoter detected in the *sigB* operon. (iv) Like the *rsbV*-*rsbW*-*sigB* cluster in *B. subtilis*, the staphylococcal orf108, orf159, and *sigB* are closely linked genes, suggesting that expression of the gene products may be translationally coupled, presumably in order to ensure equimolar synthesis of proteins which must act in concert in the cell.

Numerous observations and speculations have been described concerning the functioning of *B. subtilis* *sigB*, such as induction of  $\sigma^B$  activity upon entry into the stationary phase (14) or by environmental stress during logarithmic growth (4), control of  $\sigma^B$  activity through stationary-phase signals (2, 4), and possible roles in the induction of general stress genes (27). However, null mutants in the  $\sigma^B$  structural gene (*sigB*) did not show any obvious growth or sporulation phenotype (3, 8, 13, 14), and therefore the physiological function of  $\sigma^B$  in *B. subtilis*

FIG. 4. Genetics Computer Group Bestfit amino acid sequence comparisons. (a) orf333 and RsbU (39% identity and 62% similarity); (b) orf108 and RsbV (42% identity and 67% similarity); (c) orf159 and RsbW (54% identity and 71% similarity); SigB of *S. aureus* and SigB of *B. subtilis* (59% identity and 77% similarity). The residues critical for protein function, Gly-93 in RsbV and Ala-14 in RsbW, are in boldface. Vertical bars indicate identical amino acids; colons and periods indicate two degrees of similarity of amino acids.

remains to be identified. A *sigB*-like gene, apparently involved with the stationary phase, has recently also been identified in *Mycobacterium tuberculosis* (6).

The most striking difference between the *sigB* mutants RUSA122, -150, and -168 and the parental strain COL is the drastic reduction of antibiotic resistance in the mutants: the MIC of the parental strain was 1600 µg ml<sup>-1</sup>, whereas MICs were 25 µg ml<sup>-1</sup> for RUSA168 and 50 µg ml<sup>-1</sup> for RUSA122 (5). The decreased resistance to methicillin in RUSA168 and RUSA122 was not related to a reduction in the cellular amounts of PBP2A (the gene product of *mecA*). Moreover, in contrast to several other auxiliary or *fem* mutants, no alteration in the mucopeptide composition of the peptidoglycans of mutant RUSA168, -122, or -150 could be detected (unpublished observations).

The mechanism through which inactivation of the *sigB* cluster results in the suppression of the methicillin resistance phenotype is currently under investigation in our laboratory. Our observation that inactivation of a cluster of staphylococcal stress response genes also inactivates antibiotic resistance introduces the possibility that for optimal expression of antibiotic resistance, staphylococci require an uninterrupted functioning of stress response genes which, presumably, are activated by the metabolic disturbances induced in the cells during exposure to the antibacterial agent.

**ACKNOWLEDGMENTS**

Partial support for these studies came from the Aaron Diamond Foundation.

We thank Charles Moran, Jr., and Adriano Henriques for helpful discussions and suggestions.
