Received 14 February 2001/Accepted 5 July 2001

This study describes the characterization of the recently described *Salmonella* genomic island 1 (SGI1) (D. A. Boyd, G. A. Peters, L.-K. Ng, and M. R. Mulvey, FEMS Microbiol. Lett. 189:285–291, 2000), which harbors the genes associated with the ACSSuT phenotype in a Canadian isolate of *Salmonella enterica* serovar Typhimurium DT104. A 43-kb region has been completely sequenced and found to contain 44 predicted open reading frames (ORFs) which comprised ~87% of the total sequence. Fifteen ORFs did not show any significant homology to known gene sequences. A number of ORFs show significant homology to plasmid-related genes, suggesting, at least in part, a plasmid origin for the SGI1, although some with homology to phage-related genes were identified. The SGI1 was identified in a number of multidrug-resistant DT120 and *S. enterica* serovar Agona strains with similar antibiotic-resistant phenotypes. The G+C content suggests a potential mosaic structure for the SGI1. Emergence of the SGI1 in serovar Agona strains is discussed.

Multiple-drug-resistant (MDR) *Salmonella enterica* serovar Typhimurium phage type DT104 (hereafter abbreviated as Typhimurium DT104) is currently the second most prevalent *Salmonella* serotype isolated in England and Wales (35, 36) and is increasingly prevalent in the United States (15, 18) and Canada (26). Outbreaks of MDR Typhimurium DT104 have also been reported in poultry, beef, cheese, and swine in numerous countries (9, 12, 16, 24, 39). This strain is resistant to a core group of antimicrobials, including ampicillin, chloramphenicol, streptomycin, sulfonamides, and tetracycline (commonly abbreviated ACSSuT); however, isolates have been identified which are also resistant to fluoroquinolones, trimethoprim, and kanamycin (25, 34).

Many isolates of Typhimurium DT104 conferring the ACSSuT phenotype have a similar genetic makeup comprised of the *floR* and *tet(G)* genes bracketed by two class 1 integrons carrying the *pse-1* and *aadA2* cassettes clustered on a 14-kb region of the Typhimurium DT104 genome (3, 5, 25, 28, 30). Cotransduction experiments using P22-like phages ES18 and PDT17 demonstrated the antimicrobial resistance gene clustered on a fragment of less than 46 kb (31). Recently, this region, termed *Salmonella* genomic island 1 (SGI1), has been cloned from the genome of a Canadian isolate and has been shown to be comprised of a 43-kb region between *thdF* and a novel retron sequence (4). The genomic location, the fact that the resistance cannot be

transferred (37), and the demonstration that excision cannot be detected at the genetic level (4) has led to speculation that even if antimicrobial selective pressure is removed, the resistance will persist (4, 23, 37). However, it should be noted that persistence of the antibiotic resistance genes depends on the relative fitness cost in the absence of antimicrobials. MDR Typhimurium DT104 isolates from different countries that harbor the *pse1* and *aadA2* integrons have been shown to be similar using several molecular typing techniques, and this has led investigators to suggest a clonal dissemination of this organism (4, 10, 11, 21, 30). Recently, a number of *S. enterica* serovar Agona (hereafter referred to as Agona) strains have been characterized as harboring the same antimicrobial resistance region, suggesting horizontal gene transfer of this region (8).

Some questions exist about the nature of possible increased virulence of drug-resistant DT104 strains. Case control studies have suggested that MDR Typhimurium DT104 is possibly a hypervirulent strain compared to susceptible strains of Typhimurium DT104 or other *Salmonella* serotypes (12, 33, 39). However, this virulence does not appear to be related to a hyperinvasive phenotype as shown in tissue culture assays, as resistant DT104 is no more invasive than susceptible serovar Typhimurium strains with or without exposure to antibiotics (6, 7). Thus, as suggested, the overall pathogenicity may be enhanced by invasion-independent virulence-related factors, one of which may be treatment failure due to multidrug resistance (7).

In an attempt to identify genetic factors responsible for the increased virulence and to obtain a better understanding of the

origins of the SGII, we have sequenced the entire genomic island harboring the resistance genes as well as analyzed other MDR strains of *Salmonella* to determine if the drug-resistant genes are associated with SGII.

MATERIALS AND METHODS

Bacteria, bacteriophages, and media. The *Salmonella* strains used in this study are listed in Table 1. *Escherichia coli* LE392 was used for propagating phages, *E. coli* XL1-Blue and plasmid pBluescript II (Stratagene) were used in cloning experiments, and λ EMBL3 (Promega) was used in phage cloning experiments. All strains were grown at 37°C in brain heart infusion broth or Luria-Bertani (LB) medium. Stock cultures were stored at -70°C in Microbank vials (Pro-Lab Diagnostics, Richmond Hill, Ontario, Canada).

Antimicrobial susceptibility testing. The strains were tested for their antibiotic susceptibility on Mueller-Hinton agar by the disk diffusion method. Resistance to the following antibiotics was tested with disks containing ampicillin (10 μ g),

chloramphenicol (30 μ g), florfenicol (30 μ g), spectinomycin (100 μ g), streptomycin (10 IU), sulfonamides (200 μ g), and tetracyclines (30 IU). The media and disks were from Sanofi Diagnostics Pasteur (Marnes-la-Coquette, France), except for disks with florfenicol, which were purchased from Schering-Plough Santé Animale (Segré, France).

Recombinant DNA methodology. Genomic DNA was isolated as previously described (4). A genomic DNA library was constructed in λ EMBL3 using 15- to 20-kb *Sau*3A genomic DNA fragments from serovar Typhimurium 96-5227, and clones spanning the entire SGII were isolated as previously described (4) (Fig. 1). Templates for sequencing were obtained by subcloning various fragments from lambda clones into pBluescript II (Stratagene) (Fig. 1) and by PCR of specific regions using primers designed on previously sequenced DNA. In addition, a ~8.7-kb amplicon was obtained by long PCR using the primers St31-Not, 5'-*TAA*TgcccgcAAGCAATAGCCAGTACGCTG-3', and p134-Not, 5'-*AATA*gcccgcTCTCCGATGCTGTGCGAATG-3' (italics indicate non-*Salmonella* sequence; lowercase indicates a *Not*I site), digested with *Not*I and cloned into pBluescript II. The resulting plasmid, pNOT (Fig. 1), was then subjected to

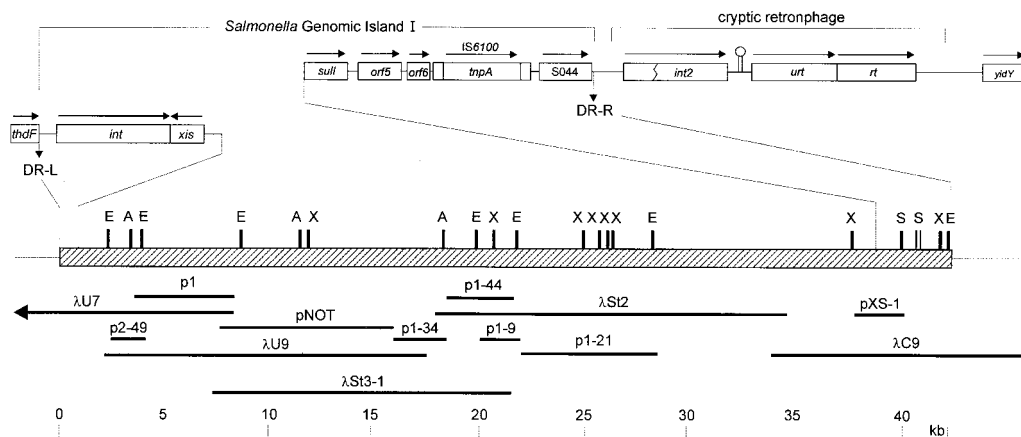

FIG. 1. Cloning strategy of the complete SGII. Letters above the map indicate restriction enzyme sites. X, *Xba*I; E, *Eco*RI; S, *Sal*I; A, *Ava*II. Boxes above the map depict previously characterized regions (4) and are not drawn to scale. Arrows denote the direction of transcription.

^a Significant homology is defined as an E value of $\leq 1e-05$ and/or $>20\%$ identity over at least 60% of the length of the protein.

^b ORFs of at least 180 bp (≥ 60 amino acids). Named ORFs are based on those previously characterized or designated here based on a putative function.

^c Nucleotide position in the sequence deposited under accession no. AH261825.

^d Expect value. Values of 0.0 were as returned by BLAST.

^e % Identity as returned by BLAST search and range (number of amino acids and gaps) over which identity value was calculated.

random mutagenesis using the EZ::TN Insertion System (Epicentre Technologies) to allow for rapid sequencing of the insert. Synthesis of oligonucleotides and DNA sequencing were carried out in the DNA Core Facility, National Microbiology Laboratory, Health Canada, Winnipeg, Canada. Standard PCRs were carried out using 2.5 U of AmpliTaq Gold DNA polymerase in PCR Buffer II (PE Applied Biosystems) containing 3 mM MgCl₂, 0.2 mM deoxynucleoside triphosphates, 0.5 μM concentrations of primers, and 50 ng of DNA. PCR cycling conditions were 95°C for 10 min followed by 30 cycles of 94°C for 30 s, 55°C for 30 s, 72°C for 1 min, and a final extension at 72°C for 5 min. Other annealing temperatures may have been used depending on the melting temperature (*T_m*) of the primers in the reaction mixture. Long PCR was carried out using the Expand Long Template PCR System (Roche Diagnostics, Laval, Quebec) as recommended by the manufacturer. Plaque and Southern blotting was carried out by standard methods (29) with probes labeled and detected by ECL kits using the manufacturer's instructions (Amersham Pharmacia Biotech).

IRS-PCR. (i) Adapters and primers. Infrequent restriction site (IRS)-PCR was performed as described previously by Mazurek et al. (22) with some modification. In brief, the *HhaI* adapter (AH), which consists of a 22-base oligonucleotide (AH1; 5'-AGA ACT GAC CTC GAC TCG CACG-3') with a 7-base oligonucleotide (AH2; 5'-TGC GAG T-3'), and the *XbaI* adapter (AX), which

consisted of a phosphorylated 18-base oligonucleotide (AX1; 5'-PO4 -CTA GTA CTG GCAGAC TCT-3') with a 7-base oligonucleotide (AX2; 5'-GCC AGT A-3'), were designed to ligate specifically to the cohesive ends of the corresponding restricted fragments. To prepare the adapters, oligonucleotides AH1 and AH2 or AX1 and AX2 were mixed in equal molar amounts in 1× PCR buffer (Promega) and were allowed to anneal as the mixture cooled from 95°C to room temperature over 1 h. The mixture was briefly centrifuged and was stored at -20°C until use.

(ii) Preparation of template DNA. One microgram of DNA was digested with 10 U of *XbaI* (QuantumAppligene) and 10 U of *HhaI* (QuantumAppligene) in 1× buffer II for 120 min at 37°C in a volume of 15 μl. Sterile distilled water, 1.5 U of T4 DNA ligase (Boehringer Mannheim), 1× ligase buffer, the *XbaI* adapter (20 pmol), and the *HhaI* adapter (20 pmol) were added for a total volume of 20 μl. The mixture was incubated at 16°C for 90 min and then at 65°C for 20 min to inactivate T4 DNA ligase. The sample was redigested with 5 U of *XbaI* and 5 U of *HhaI* at 37°C for 15 min to cleave any restriction sites re-formed by ligation and then submitted to amplification.

(iii) PCR amplification. Each PCR mixture included 2.5 μl of a 1:10 dilution of template DNA, 0.5 U of *Taq* DNA polymerase (Promega), deoxynucleoside triphosphates (50 mM each) (Promega), and the oligonucleotide primers in 1×

PCR buffer. Typically, the oligonucleotides AH1 and 6-carboxyfluorescein (Fam)-labeled PX were used together as primers. Amplification was performed in a GeneAmp 9700 thermocycler (Perkin-Elmer) with an amplification profile that consisted of an initial denaturation step at 94°C for 5 min and then 30 cycles of denaturation at 94°C for 30 s, primer annealing at 60°C for 30 s, and extension at 72°C for 90 s. All experiments included negative controls, which were processed with the samples.

(iv) **Separation of PCR products.** Following amplification, 1 to 1.5 µl of undiluted IRS-PCR product was mixed with 0.5 µl of internal lane standard (Genescan-Rox 500; PE Applied Biosystems), and deionized formamide was added to a final volume of 20 µl. The resulting mixture was heated at 95°C for 4 min and then quickly cooled on ice. Separation and detection of 6-carboxy-fluorescein (Fam)-labeled PCR products were performed by capillary electrophoresis on an ABI 310 automated sequencer, and electrophoresis was conducted for 30 min per sample at 60°C as described by the manufacturer.

(v) **Data capture and analysis.** The results were automatically collected with the Genescan collection and fragment analysis software. The internal lane standards, included in each lane, allowed an accurate sizing of individual IRS-amplified fragments. The results were viewed in the form of an electrophoregram, tabular data, or a combination of both. Interpretation of Genescan data was performed using the Genotyper software, which allowed construction of tabular binary data based on presence or absence of bands between each studied strain. The Genotyper analysis parameters were set to medium smoothing, and the baseline fluorescence was set to 150 U. The software filter used to remove PCR and background noise was as follows: "remove labels from peaks preceded by higher (at least 5%), labeled peak within 0 to 2.5 bp, and remove labels from peaks followed by higher (at least 5%), labeled peak within 0 to 2.5 bp." IRS-PCR similarities between strain pairs were calculated using the Jaccard coefficient, and cluster analysis was performed using the unweighted pair group method with averages (UPGMA) algorithm (33).

Computer-aided analysis and annotation. Homology searches were carried out using the BLAST suite of programs (2), and open reading frames (ORFs) were detected with ORFinder via the World Wide Web interface of the National Center for Biotechnology Information (<http://www.ncbi.nlm.nih>). All ORFs larger than 180 bp (more than 60 amino acids) were used as queries in BLAST searches. Significant homology was defined as an expect value (E value) of <1e-05 (e means exponential; 1e-05 is 0.00001) for the top-scoring protein and/or >20% identity over at least 60% of the length of the protein.

Nucleotide accession number. The complete nucleotide sequence of SG11 has been deposited in the GenBank database under accession number AF261825.

RESULTS AND DISCUSSION

General properties of the SG11 sequence. Overlapping lambda clones and plasmids used in this study are shown in Fig. 1. The complete sequence of the 42,415-bp region between the previously characterized direct repeats DR-L and DR-R, which define the boundaries of the genomic island inserted between the *thdF* gene and a cryptic retronphage in the Typhimurium DT104 genome (4), has been determined. A total of 44 ORFs initiated by 42 putative ATG, 1 TTG (S023), and 1 CTG (S036) start codons have been identified. Table 2 lists the ORFs whose putative products show similarity to protein sequences available in GenBank, and Table 3 lists the ORFs whose putative products show no significant similarity to available protein sequences. Figure 2 depicts a linear map with all ORFs labeled with some named based on function, and the putative functions of others are indicated. No conclusions regarding whether S017, which overlaps S016 and S018, is an expressed ORF or vice versa, though the latter two are preceded by putative Shine-Dalgarno sequences while S017 is not. Similarly, S021 and S022, which overlap by 88 bp, are likely mutually exclusive as ORFs, though S022 is preceded by a putative Shine-Dalgarno sequence while S021 is not. Nonetheless, the putative ORFs account for ~87% of the SG11 sequence.

Overall the G+C content for SG11 is 49.17%, compared

TABLE 3. The ORFs in SG11 DNA whose deduced products showed no significant homology^a to extant protein sequences

S044	41840–42469	630	209	47.3

^a No significant homology was defined as an E value of >1e-2 for the top-scoring hit in a BLAST search.

^b ORFs of at least 180 bp long (≥60 amino acids).

^c Nucleotide position in the sequence deposited under accession no. AF261825.

with 51 to 53% for the *S. enterica* Typhimurium genome (Fig. 3) (27). Within SG11, regions of different G+C content can be identified, notably the MDR region (S028 to S042), which is 58.7% G+C, although within this region the *pse-1* gene is 41% G+C. The region encompassing S001 to S027 is 44% G+C, although within this region the S020 to S022 region is 53.2% G+C. Thus even outside of the MDR region a mosaic structure is indicated.

The multidrug resistance region. The MDR region of Typhimurium DT104 96–5227 (S028 to S042) has previously been characterized by PCR mapping and partial sequencing (4, 25) and has been found to be similar in content and gene order to that in other Typhimurium DT104 isolates displaying a pentaresistance phenotype (3, 5, 30, 34). Essentially, the *floR* gene (S032) and the *tetR-tet(G)* genes (S033 to S034) are bracketed by two class I integrons, one containing an *aadA2* cassette (S028 to S031) and the other a *pse-1* cassette (S037 to S042). A resolvase gene, *tnpR*, is located upstream of the *aadA2* integron. Two additional genes, *orf1* (S035), encoding a putative *lysR*-type transcriptional regulator, and *orf2* (S036), carrying a transposase-like gene, are also found in this region. We have, however, detected a number of nucleotide differences between the 96–5227 sequence in this region and the sequences from other strains. In bovine Typhimurium DT104 strain BN9181 isolated in Europe, the published sequence of the *tnpR* gene (accession no. AF121001) contains an extra T in the position equivalent to that beside the T at position 26051 of the 96–5227 sequence (for base pair coordinates refer to accession no. AF261825) and which introduces a stop codon at this point in the BN9181 sequence (3). Thus, the predicted BN9181 TnpR protein is 172 amino acids, while that of 96–5227 is 194 amino acids. This extra T is absent in the human clinical Typhimurium DT104 strain H3380 (accession no. AF071555) isolated in the USA (5), which, however, has a G instead of a C at the position equivalent to position 26054 of the 95–5227 sequence. This results in an amino acid difference at residue

FIG. 2. Linear representation of the complete SG11 and flanking regions. Upper rectangles indicate ORFs transcribed from right to left, and lower rectangles are transcribed left to right. GenBank entries of ORFs were assigned unique identifiers in the form SXXX. Color coding indicates ORFs with similar function as follows: green, DNA recombination; black, DNA replication; yellow, conjugal transfer; blue, regulatory; red, drug resistance; white, not known or other functions.

171 of the TnpR protein, with 96–5227 having an arginine here (as does BN9181) and H3380 a proline. In the *aadA2* gene region, strain 96–5227 has a G at position 28211, while a C is found in strain H3380, resulting in a difference at residue 72 with a glutamic acid in 96–5227 substituted for a lysine in H3380. Upstream of the *floR* gene, the published sequence from BN9181 (accession no. AF118107) contains an extra A at a position equivalent to one between 30350 and 30354 of the 96–5227 sequence. The extra base, absent in the H3380 sequence, is in a noncoding region and would appear not to have

any functional significance. Within the *floR* gene itself we have found two nucleotide differences between the 96–5227 and H3380 sequences. Position 30679 is a G in 96–5227 and an A in H3380 but results in no change in residue 66 of the FloR protein, which is a glutamine in both strains. Position 31299 is a C in the 96–5227 sequence and a T at the equivalent position in the H3380 sequence, which results in residue 273 being alanine in the 96–5227 FloR protein and valine in the H3380 protein. The BN9181 FloR protein sequence is identical to that of the 96–5227 protein sequence. Finally, strain 96–5227 has an

FIG. 3. G+C content of the SGI1. MDR and RT represent the multidrug resistance and retron sequences, respectively.

A at position 34842, which is absent in H3380 and results in a change in reading frames here between the *orf2* genes such that the predicted 96–5227 Orf2 transposase-like protein consists of 494 residues while the predicted H3380 protein consists of 531 residues.

The region between the *pse-1* integron and DR-R has been previously characterized (accession no. AF261825) and contains the only insertion element found in SGI1, namely IS6100, and an ORF, S044 (previously designated Sgi1), encoding a hypothetical protein (4).

The remainder of SGI1. A number of ORFs have been identified which show similarity to plasmid genes involved in mating pair formation and DNA transfer. Three ORFs, S005, S0011, and S012, have putative products that showed similarity to the mating pair stabilization protein TrhN and the pilus assembly proteins R0128 and TrhH, of the IncH plasmid R27 found in *S. enterica* serovar Typhi and other *Enterobacteriaceae*, respectively (32). The S023 product shows similarity to bacterial DNA helicases, and the S026 product shows similarity to an ATPase from the *Rhizobium* symbiosis plasmid pNGR234a (14). Interestingly, the Tra2 region of pR27 contains a helicase (TrhI) and an ATPase (TrhC), the latter of which is involved in pilus synthesis and assembly. The C-terminal region of the S025 product, which exhibits similarity to the N-terminal region of the Y4BN hypothetical protein of pNGR234a, contains a peptidase (S8) conserved domain from the subtilase family of proteinases. The S003 product exhibits similarity to the DNA replication protein RepA from the *Rhodospseudomonas* plasmid pMG101 (19). The S024 product is similar to the phage P2 OLD protein, which may be an exonuclease involved in overcoming defects in lysogenization (19). One other ORF product, that of S020, showed similarity to a plasmid protein of unknown function, Orf3, from the *Francisella* plasmid pFNL10 (AF121418). At least one regulator protein has been identified in this region, the product of S006, which shows similarity to a transcriptional activator regulating flagellum biosynthesis in *Bordetella bronchiseptica* (1).

The region between DR-L and S003 has been previously characterized (accession no. AF261825) (4) and found to contain two ORFs, S001 and S002, encoding a putative integrase (*int*) and excisionase (*xis*), respectively.

We could find no significant homology to proteins in GenBank for the putative products of 15 other ORFs in SGI1

(Table 3). Attempts to identify putative origins of replication (*ori*) were not successful.

Distribution of SGI1 amongst serovars Typhimurium DT104 and DT120 and Agona with various resistance profiles. Genetically diverse strains, as determined by IRS-PCR (Fig. 4), of pentaresistant Typhimurium DT104, DT120, and Agona, as well as Typhimurium DT104 with different MDR profiles, were analyzed by PCR to determine the presence of SGI1 (Table 1). PCR to detect the left junction (*thdF*-S001) was carried out with the primer pair U7-L12 and LJ-R1, and PCR to detect the right junction (S044-*int2* or S044-*yidY*) was car-

FIG. 4. Clustering of *Salmonella* isolates by analysis of IRS-PCR patterns. The dendrogram was constructed by UPGMA on a matrix based on Jaccard's coefficient. Strains were isolated in Belgium (B), France (F), or Scotland (S).

TABLE 4. Primers used in this study

Name	Sequence (5' to 3')
U7-L12	ACACCTTGAGCAGGGCAAAG
LJ-R1	AGTTCTAAAGGTTTCGTAGTCG
104-RJ	TGACGAGCTGAAGCGAATTG
C9-L2	AGCAAGTGTGCGTAATTTGG
104-D	ACCAGGGCAAACACTACACAG
QS-1	ATGAAAGGCTGGCTTTTCTTG
QS-2	TGAGTGCATAACCACCAGCC

ried out with the primer pair 104-RJ and C9-L2 or 104-RJ and 104-D (Table 4). All drug-resistant strains produced a product of the expected size for the left junction (*thdF*-S001), while the serovar Typhimurium strains were positive for the right junction (S044-*int2*) and the Agona strains were positive for the S044-*yidY* product. Drug-sensitive strains were negative for the above PCRs. Thus, in Agona strains SGI1 appears to be inserted at the 3' end of the *thdF* gene as in serovar Typhimurium strains, but they do not contain the cryptic retron-phage in the *thdF-yidY* intergenic region (4). Southern hybridization analysis of *XbaI* digests of the above strains was carried out using the 2-kb *EcoRI* fragment from p1-9 and the *qacEdeltaI/sulI* amplicon produced using primers QS-1 and QS-2 (Fig. 2). The 2-kb *EcoRI* fragment probe hybridized with the 9-kb and 4-kb *XbaI* fragments in the resistant strains as expected, while sensitive strains did not show any hybridization signals (Table 1). The *qacEdeltaI/sulI* probe hybridized with the 11.7-kb fragment containing most of the MDR region in all the pentaresistant serovar Typhimurium and Agona strains, but only in the serovar Typhimurium strains and Agona 959SA97 did the expected 4.3-kb fragment at the right end of SGI1 hybridize (Table 1). In three other Agona strains besides the 11.7-kb fragment, a fragment of about 8.4 kb hybridized, suggesting that an additional 4 kb of DNA was present in this region (Table 1). This larger-than-expected product was not due to deletion of the *XbaI* site in S044 as determined by sequence analysis (data not shown). In the serovar Typhimurium strains containing the single integron S/960725 (ASu), a 4.3-kb fragment hybridized, and in S/954435 (SSu) a 7-kb fragment hybridized with the *qacEdeltaI/sulI* probe. Analysis of these strains is being undertaken to determine the nature of the variant MDR regions. Thus, from the results above, it appears that all drug-resistant strains in this study harbor SGI1. However, some variability exists in the MDR region, suggesting a high level of recombination can occur in this particular region of SGI1.

The SGI1 is flanked by an imperfect 18-bp direct repeat which appeared to be a duplication of the last 18 bp of the *thdF* in strain 96-5227 (Fig. 2) (4). This type of direct repeat is

FIG. 5. Alignment of the direct repeats (DR) flanking the SGI1 in serovars Typhimurium and Agona. Asterisks represent nucleotide substitutions (see the text). sen, sensitive; res, resistant.

similar to those found in pathogenicity islands (17). Sequence analysis of the left and right junctions of Agona 1146SA97 also revealed a similar structure. However, comparison of the direct repeats from these two strains with *thdF* sequences from respective sensitive strains has revealed some interesting findings. The DR-R sequence is identical to the sequence from the respective *thdF* sequences from sensitive serovar Typhimurium or Agona strains, suggesting the origin of the DR-R is actually the end of *thdF* (Fig. 5). These sequences are slightly divergent between serovar Typhimurium and Agona, with a T located at position 9 of the direct repeat in serovar Typhimurium as opposed to a C at this position in Agona. The DR-L sequence is identical in both serotypes, suggesting the origin of this sequence may be from the donor DNA and not the result of a duplication event. Taken together, these results suggest that the SGI1 insertions were separate events and not a result of genetic exchange between the two serotypes.

The possible independent emergence of MDR Typhimurium and Agona serotypes suggests this multidrug phenotype may emerge in other strains of *Salmonella*. If this region also carries genes responsible for increased virulence or transmission possibly observed with MDR Typhimurium DT104 (see below), the spread of other phage-types or serotypes acquiring this unique region may be observed in the future. The ACSSuT phenotype has been identified on a transferable 140-kb plasmid in non-phage-typeable strains of serovar Typhimurium (38). The plasmid was shown to contain integrons other than the ones described here, suggesting SGI1 did not originate from this plasmid. An *S. enterica* serovar Typhi strain has been described harboring the ACSSuT phenotype on a 98- to 100-MDa transferable plasmid (20). It will be interesting to determine the genes responsible for this phenotype and if any homology exists between this plasmid and SGI1.

Infections associated with MDR Typhimurium DT104 have been associated with higher rates of admission to hospitals and mortality than other salmonellas (40). In addition, a study involving a small number of infections with MDR Typhimurium DT104 demonstrated a higher number of blood infections compared to those with sensitive strains (23). We could not identify any ORFs whose products might be directly related to pathogenesis in the SGI1 and possibly explain the increase in virulence demonstrated by the above studies. It is interesting to note the similarities of SGI1 to pathogenicity islands. Both harbor large segments of DNA flanked by small direct repeats which have different G+C contents compared to the chromosomal DNA, and both harbor cryptic and functional genes encoding mobility factors (17 and this study). Although no virulence factors were identified in SGI1, this study has revealed 15 potential ORFs with no homology to any known gene (Table 3), which may function as potential virulence factors. Both in vitro and in vivo studies are under way to try to elucidate the role, if any, of the SGI1 in virulence.
